PACS 64.60.My – Metastable phases

Abstract. -

The Hamiltonian Mean Field (HMF) model is a paradigmatic toy model for long-range Hamiltonian system, which has raised recently a great attention and has been investigated in detail, see for example [2] and references therein. We have recently published two papers on this model [3,4] concerning the possible application of a generalized version of the Central Limit Theorem (CLT) in accordance with q -statistics [5–8]. In these papers, following ref. [7], we constructed probability density functions (Pdf) of quantities y 's expressed as a finite sum of n stochastic variables, selected along the deterministic time evolutions of the N rotors at fixed time intervals δ . We found that, along the metastable quasistationary states (QSS) of the HMF model, q -Gaussian-like Pdfs appear to emerge as attractors [3,4]. In ref. [1] the authors advance several misleading claims suggesting that the results found in papers [3,4] are erroneous and that no q -Gaussian attractors exist for correlated variables extracted from HMF dynamics. Two crucial points raised by Figueiredo et al. are the following: (i) by doing the calculations with more accuracy and better statistics, it would be possible to show that a q -Gaussian attractor does not exist, since there is an evident cut-off in the tails of the final distributions; (ii) by considering increasingly large size systems, the Pdf would gradually converge to a Gaussian. The point (i), which is illustrated in fig.1 of [1], can be easily rebutted by considering that, like the usual CLT, the q -CLT strictly applies only if n goes to infinity. In the example shown in [1] only $n = 50$ (with $N = 100$ and $\delta = 40$) was considered, therefore one expects deviations in the tails, and elsewhere. Here we present new calculations for the case $N = 20000$, which indicate that this phenomenon is true whatever is the shape of the final attractor. It is also important to remind that, in ref. [4] (ref. [33] of [1]), we

observed the existence of three classes of trajectories for the same water-bag (M1) initial conditions, each one of them showing a different central limit behavior: class 1, with a q -Gaussian-like attractor, class 3 with a Gaussian attractor and class 2 with an intermediate behavior. In the upper row of fig.1 we show the Pdf of a typical event of class 1 for three increasing values of n ($n = 200$, $n = 1000$ and $n = 2000$), while in the middle row the corresponding behavior is illustrated for a typical event of class 3, for the same values of n . Being in all the simulations $\delta = 100$, the sums have been performed, respectively, for 20000, 100000 and 200000 time steps. The time evolution for the temperature in both cases is plotted in the bottom panel. Notice that the cut-off in the tails of the distributions, clearly visible for $n = 200$, disappears slowly by increasing the number of summands n , in both cases. The convergence starts, for small n , from the central part of the Pdf and then extends to the tails, producing in one case (class 3) a Gaussian-like and, in the other case (class 1), a q -Gaussian-like curve as a final attractor. The other main point addressed by fig.1 is that at least two kinds of attractors coexist in the QSS regime and their occurrence, as discussed in ref. [4], depends very sensitively on the different realizations of the initial conditions. The authors of ref. [1], although quoting our paper, fail in taking into account this fundamental point: in their fig. 3 they consider a system of $N = 100000$ rotators and plot a Pdf for 50 events without any reference to their corresponding class, and it is evident that the trajectories used belonged to a random mixture of classes 1, 2 and 3 (see [4]). Actually, mixing events or not distinguishing between events of different classes leads to unreliable conclusions, since the dynamics and the correlations of the various trajectories can be very different. We notice that although the

Fig. 1: Time evolution of two events with the same M1 initial conditions, more precisely with $N = 20000$ at $U = 0.69$, but belonging to different classes (1 and 3). The evolution towards the final attractor appears to be a Gaussian-like for the event of class 3 and a q -Gaussian-like for the event of class 1. The q -Gaussian is a generalization of Gaussian which emerges in the context of nonextensive statistical mechanics [5] and is defined as $G_q(x) = A(1 - (1 - q)\beta x^2)^{1/(1-q)}$. Here we have $q = 1.42 \pm 0.1$, $\beta = 1.3 \pm 0.1$ and $A = 0.55$, and the resulting curve is plotted in all the panels together with a standard Gaussian. See text for further details.

events of class 1 seem to diminish with N , those of class 2 increase more than those of class 3 [4]. Finally, in order to address point (ii) of the criticism raised in ref. [1], we illustrate in fig. 2 how the attractor shown in the upper row of fig. 1 evolves its shape by increasing both the size of the system N and, consistently, the number of summands n , but leaving constant the ratio N/n . This latter choice is however not a necessary condition, here it is done only because the QSS lifetime increases with N . The calculations refer here to three typical events of class 1 with sizes $N = 10000, 50000$ and 100000 (note that the range of the ordinate was enlarged with respect to fig. 1). The gradual filling of the tails by increasing N strongly suggests that, for N and n going to infinity, a q -Gaussian-like asymptotic shape might well be eventually reached, thus reinforcing its role of real attractor for the QSS regime. In conclusion, the evidence presented in [1] by no means invalidates the occurrence of the q -generalized CLT for the HMF system and in general for long-range Hamiltonian systems. On the other hand, if these systems are non-ergodic (as the authors themselves admit and as we believe we have clearly established [3, 4]), it also remains unclear why should one not expect, for the time-averaged distribution, a non-Gaussian attractor in the QSS regime. In summary, we presented further numerical evidence that standard statistical mechanics has severe problems in explaining the anomalous long-standing QSS regime of the

Fig. 2: For $U = 0.69$ we show the Pdfs obtained considering single events of class 1 for different sizes N , with $\delta = 100$ and $n = N/10$. Again the indications for a q -Gaussian-like attractor becomes stronger and stronger when sending both N and n to infinity. See text for further details.

HMF model, showing that in this respect q -statistics remains a very good candidate.
